THE VLT-FLAMES TARANTULA SURVEY: THE FASTEST ROTATING O-TYPE STAR AND SHORTEST PERIOD LMC PULSAR – REMNANTS OF A SUPERNOVA DISRUPTED BINARY?

P.L. Dufton[1], P.R. Dunstall[1], C.J. Evans[2], I. Brott[3], M. Cantiello[4,5], A. de Koter[6] S.E. de Mink[7*], M. Fraser[1], V. Hénault-Brunet[8], I.D. Howarth[9], N. Langer[4], D.J. Lennon[10], N. Markova[11], H. Sana[6], W.D. Taylor[8]

ABSTRACT

We present a spectroscopic analysis of an extremely rapidly rotating late O-type star, VFTS102, observed during a spectroscopic survey of 30 Doradus. VFTS102 has a projected rotational velocity larger than $500\,\mathrm{km\,s^{-1}}$ and probably as large as $600\,\mathrm{km\,s^{-1}}$; as such it would appear to be the most rapidly rotating massive star currently identified. Its radial velocity differs by $40\,\mathrm{km\,s^{-1}}$ from the mean for 30 Doradus, suggesting that it is a runaway. VFTS102 lies 12 pcs from the X-ray pulsar PSR J0537-6910 in the tail of its X-ray diffuse emission. We suggest that these objects originated from a binary system with the rotational and radial velocities of VFTS102 resulting from mass transfer from the progenitor of PSR J0537-691 and the supernova explosion respectively.

Subject headings: stars: early-type — stars: rotation — stars: evolution — Magellanic Clouds — pulsars: individual (PSR J0537-6910)

1. INTRODUCTION

In recent years the importance of binarity in the evolution of massive stars has been increasingly recognised. This arises from most OB-type stars residing in multiple systems (Mason et al. 2009) and the significant changes to stellar properties that binarity can cause (see, for example, Podsiadlowski et al. 1992; Langer et al. 2008; Eldridge et al. 2011).

Here we present a spectroscopic analysis of a rapidly rotating ($v_{\rm eq}\sin i \sim 600\,\mathrm{km\,s^{-1}}$) O-type star in the 30 Doradus region of the Large Magellanic Cloud (LMC). Designated VFTS102 (Evans et al. 2011, hereafter Paper I)[13], the star is rotating more rapidly than any observed in recent large surveys (Martayan et al. 2006; Hunter et al. 2009) and may also be a runaway. It lies less than one arcminute from the X-ray pulsar, PSR J0537-6910, which is moving away from it.

We suggest that VFTS102 might originally have been part of a binary system with the progenitor of the pulsar.

2. OBSERVATIONS

Spectroscopy of VFTS102 was obtained as part of the VLT-FLAMES Tarantula Survey, covering the 3980-5050Å region at a spectral resolving power of 7000 to 8500. Spectroscopy of the Hα region was also available, although this was not used in the quantitative analysis. Details of the observations and initial data reduction are available in Paper I.

The spectra were normalised to selected continuum windows using a sigma-clipping rejection algorithm to exclude cosmic rays. No velocity shifts were observed between different epochs, although simulations (see, Sana et al. 2009) indicate that 30% of short period (less than 10 days) and effectively all longer term binaries would not have been detected. We have therefore assumed VFTS102 to be single and the sigma-clipped merged spectrum displays a signal-to-noise ratio of approximately 130 and 60 for the 4000-4500 and 4500-5000Å regions respectively.

An O9: Vnnne spectral classification was obtained by smoothing and rebinning the spectrum to an effective resolving power of 4000 and comparing with standards compiled for the Tarantula Survey (Sana et al. in preparation). The principle uncertainties arise from the extremely large rotational broadening and significant nebular contamination of the He I lines, with the two suffixes indicating extreme line broadening (‘nnn’) and an emission-line star (‘e’).

3. ANALYSIS

3.1. *Projected rotational velocity*

The large rotational broadening of the spectral features makes reliable measurements of the projected rotational velocity, $v_{\rm eq}\sin i$, difficult. We have used a Fourier Transform (FT) approach as discussed by Simón-Díaz & Herrero (2007), supplemented by fitting rotational broadened profiles (PF) to the observed spectral features.

The Balmer lines have significant nebular emission and

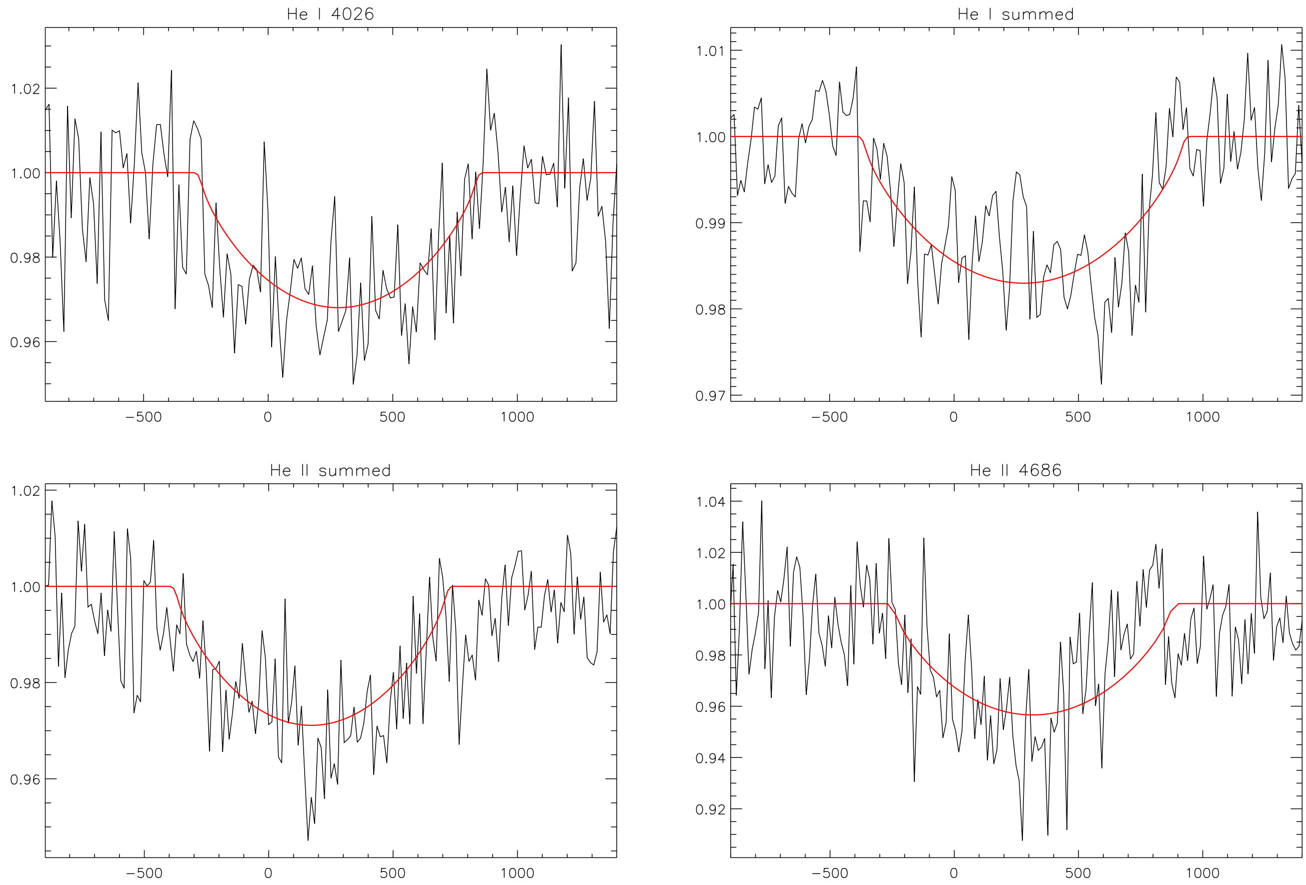

Figure 1. Observed spectra (in velocity space) for VFTS102 and rotationally broadened profiles for the He I line at 4026Å, the combined profile for the He I lines at 4026, 4143 and 4387Å, the combined profile for the He II lines at 4200 and 4541Å and the He II line at 4686Å.

hence the weaker helium spectra were utilized, as illustrated in Fig. 1. The He I line at 4471Å, although well observed, also showed significant nebular emission and was not analysed. By contrast the line at 4026Å showed no evidence of emission and yielded a plausible minimum in the Fourier Transform for a $v_{\rm eq} \sin i$ of $560\,{\rm km\,s^{-1}}$. The PF methodology leads to a slightly higher estimate ($580\,{\rm km\,s^{-1}}$). The He I lines at 4143 and 4387Å were observed although they are relatively weak. They and the line at 4026Å were converted into velocity space, merged and analysed. The two methodologies yielded effectively identical estimates of $640\,{\rm km\,s^{-1}}$; a similar procedure was undertaken for the He II lines at 4200 and 4541Å yielding $540\,{\rm km\,s^{-1}}$ (FT) and $510\,{\rm km\,s^{-1}}$ (PF). The He II line at 4686Å was found to be sensitive to the normalisation with a $v_{\rm eq} \sin i$ of $\sim 560\,{\rm km\,s^{-1}}$ being estimated.

The individual results should be treated with caution but overall they imply that this star is rotating near to its critical velocity, with the mean value for the FT estimates being $580\,{\rm km\,s^{-1}}$. As discussed by Townsend et al. (2004), projected rotational velocities may be underestimated at these large velocities. For a B0 star rotating at 95% of the critical velocity, this underestimation will be approximately 10%. Hence our best estimate for the projected rotational velocity is $\sim 600\,{\rm km\,s^{-1}}$. A lower limit of $500\,{\rm km\,s^{-1}}$ has been adopted, whilst the upper value will be constrained by the critical velocity of approximately $700\,{\rm km\,s^{-1}}$ from the models of Brott et al. (2011).

This estimate is significantly higher than those ($\lesssim 370\,{\rm km\,s^{-1}}$) found by Martayan et al. (2006) and Hunter et al. (2009) in their LMC B-type stellar samples. It is also larger than any of the preliminary estimates ($\lesssim 450\,{\rm km\,s^{-1}}$) for ~ 270 B-type stars in the Tarantula survey, although other rapidly rotating O-type stars have been identified. As such it would appear to have the highest projected rotational velocity estimate of any massive star yet analysed.

3.2. *Radial velocity*

Radial velocities were measured by cross-correlating spectral features against a theoretical template spectrum taken from a grid calculated using the code TLUSTY Hubeny (1988) – see Dufton et al. (2005) for details.

Five spectral regions were considered, viz. Hδ and Hγ (with the cores excluded); He I at 4026Å; 4630-4700Å with strong multiplets due to C III and O II and an He II line; 4000-4500Å (with nebular emission being excluded). The measurements are in excellent agreement with a mean value of $228 \pm 12\,{\rm km\,s^{-1}}$; if the error distribution is normally distributed the uncertainty in this mean value would be $6\,{\rm km\,s^{-1}}$.

From a study of $\sim$180 presumably single O-type stars in the Tarantula survey Sana et al. (in preparation) find a mean velocity of $271\,{\rm km\,s^{-1}}$ with a standard deviation of $10\,{\rm km\,s^{-1}}$. Preliminary analysis of the B-type stars in the same survey has yielded $270 \pm 17\,{\rm km\,s^{-1}}$. VFTS102

Table 1
Properties of VFTS102

Parameter	Estimate
Spectral type	O9: Vnnne
$T_{\rm eff}$ (K)	36000±5000
log g (cm s^{-2})	3.6±0.5
$v_{\rm eq} \sin i$ (km s^{-1})	600 ± 100
$v_{\rm r}$ (km s^{-1})	228±6
log L/L$_\odot$	5.0±0.2

lies more than two standard deviations away from these results, implying that it might be a runaway.

3.3. *Atmospheric parameters*

While the equatorial regions of VFTS102 will have a lower gravity than the poles (because of centrifugal forces), and hence a lower temperature (because of von Zeipel gravity darkening), we first characterise the spectrum by comparison with those generated with spatially homogeneous models, convolved with a simple rotational-broadening function. We have used both our TLUSTY grid and FASTWIND calculations (Puls et al. 2005), adopting an LMC chemical composition. For the former, the strength of the He II spectrum implies an effective temperature ($T_{\rm eff}$) of ~32500–35000 K, whilst the wings of the Balmer lines lead to a surface-gravity estimate of ~3.5 dex (cgs). For the latter after allowing for wind effects, the corresponding parameters are 37000 K and 3.7 dex. The helium spectra are consistent with a solar abundance but with the observational and theoretical uncertainties we cannot rule out an enhancement.

Given its projected equatorial rotation velocity, VFTS102 is almost certainly viewed at $\sin i \sim 1$. Hence the relatively cool, low-gravity equatorial regions will contribute significantly to the spectrum. Although their surface flux is lower than for the brighter poles, the analyses discussed above may underestimate the global effective temperature and gravity. However, the rotating-star models discussed below suggest that the effects are not very large. We therefore adopt global estimates for the effective temperature of 36000 K and 3.6 dex but note that the *polar* gravity could be as large as 4.0 dex. Varying the global parameters by the error estimates listed in Table 1 leads to significantly poorer matches between observation and the standard models, but, given the caveats discussed above, those errors should still be treated with caution.

For near critical rotational velocities, the stellar mass can be estimated. Howarth & Smith (2001) show that the stellar mass can be written in terms of $\omega/\omega_{\rm c}$[14], $v_{\rm eq}$ and the polar radius. Assuming that $\sin i \sim 1$ and adopting the critical velocities from our single star models, we can estimate the first two quantities. Additionally for any given value of $\omega/\omega_{\rm c}$, the polar radius can be inferred from the absolute visual magnitude and the unreddened (B-V). The former can be estimated from the luminosity (see Sect. 3.4) and the latter from our effective temperature estimate and the LMC broad-band intensities calculated by Howarth (2011). We find $M \gtrsim 20$ M$_\odot$ for $v_{\rm eq} \sim 600\,{\rm km\,s^{-1}}$ and $T_{\rm eff} \lesssim 38000$ K. Only by adopting a smaller value for $v_{\rm eq}$ can we push the mass limit down, but even with $v_{\rm eq} \sim 500\,{\rm km\,s^{-1}}$ the mass must exceed ~17M$_\odot$.

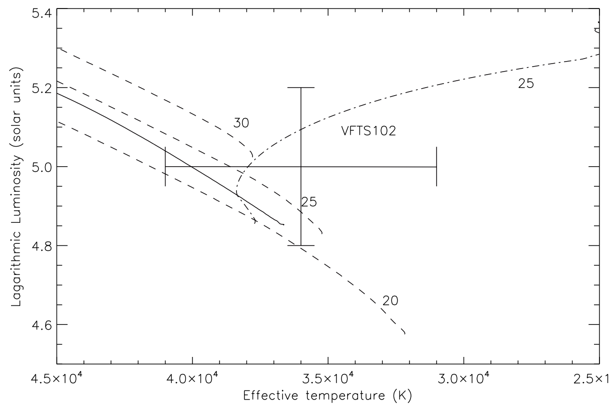

Figure 2. HR-diagram showing the estimated position of VFTS102. The evolutionary tracks (identified by their mass) have rotational velocities of approximately $600\,{\rm km\,s^{-1}}$ (dashed lines) and $400\,{\rm km\,s^{-1}}$ (dashed-dot line). Also shown is the evolution of the secondary star following mass transfer for the binary model of Cantiello et al. (2007) (solid line).

3.4. *Luminosity*

From extant photometry (see Paper I), the (B-V) colour of VFTS102 is 0.35, implying an E(B-V) of 0.6 using colours calculated from our TLUSTY grid. Adopting a standard reddening law leads to a logarithmic luminosity (in solar units) of 5.0 dex, with an E(B-V) error of ±0.1 corresponding to an uncertainty of ±0.1 dex. However there are other possible sources of error, for example deviations from a standard reddening law and hence we have adopted a larger random error estimate of ±0.2 dex.

As VFTS102 is an Oe-type star, its intrinsic colours may be redder than predicted by our TLUSTY grid and indeed an infrared excess is found from published (de-reddened) 2MASS photometry. Inspection of a K-band VISTA image shows no evidence of contamination by nearby sources. Further evidence for circumstellar material is found in the strong Hα emission, which is double peaked as is the nearby He I line at 6678Å, which supports our adoption of a $\sin i \sim 1$. Additionally there are weak double-peaked Fe II emission features (e.g. at 4233Å), consistent with an Oe-type classification. Unfortunately our photometry and spectroscopy are not contemporaneous but if VFTS102 was in a high state when the optical photometry was taken, we may have overestimated the luminosity of the central star (see de Wit et al. 2006, for colour and magnitude variations of Be stars).

4. PAST AND FUTURE EVOLUTION

Stellar evolution calculations for both single and binary stars are available in the literature (see Maeder & Meynet 2011). For very fast rotation, they suggest that rotational mixing is so efficient that stars may evolve quasi-chemically homogeneously (Maeder 1987; Woosley & Heger 2006; Cantiello et al. 2007; de Mink et al. 2009; Brott et al. 2011). However, with different physical assumptions, models do not evolve chemically homogeneously even for the fastest rotation rates (Cantiello et al. 2007; Ekström et al. 2008).

---

[14] The ratio of the equatorial angular velocity to that at which the centrifugal acceleration equals the gravitational acceleration.

4.1. *Single star evolution*

Fig. 2 illustrates evolutionary tracks for LMC single stars calculated using the methodology of Brott et al. (2011) for an initial equatorial rotational velocity of $600\,\mathrm{km\,s^{-1}}$, together with that for a more slowly rotating model. The former are evolving chemically homogeneously whilst the latter follows a ‘normal’ evolutionary path. Ekström et al. (2008) calculated models for a range of metallicities and masses between 3 and $60\,\mathrm{M_{\odot}}$ but found that the stars followed normal evolutionary paths even for near critical rotational velocities.

The estimated parameters of VFTS102 are consistent with our tracks for initial masses of $\sim$20-30$\,\mathrm{M_{\odot}}$. Our models show a relatively rapid increase in the surface helium abundance due to their homogeneous evolution. For example the $25\,\mathrm{M_{\odot}}$ model shows an enrichment of a factor of two after approximately 4 million years and when the effective temperature has increased to approximately 39000 K. By contrast the models of Ekström et al. (2008) show no significant helium abundance implying that an accurate helium abundance estimate for VFTS102 would help constrain the physical assumptions.

4.2. *Binary star evolution*

Below, we first discuss the environment of VFTS102 and then consider a possible evolutionary scenario.

4.2.1. *A pulsar near VFTS102*

VFTS102 lies in a complex environment near the open cluster NGC 2060. In particular it lies close to a young X-ray pulsar PSR J0537-6910 (Marshall et al. 1998) and the Crab-like supernova remnant B0538-691 (Micelotta et al. 2009). VFTS102 has an angular separation of approximately 0.8 arcminutes from PSR J0537-6910 implying a spatial separation (in the plane of the sky) of approximately 12 pc.

The X-ray emission consists of a pulsed localised component and a more spatially diffuse component, with the latter providing the majority of the energy. The diffuse component was identified in ROSAT and ASCA observations by Wang & Gotthelf (1998a) and interpreted as coming from ram-pressure-confined material with the X-ray pulsar being identified soon afterwards by Marshall et al. (1998). Wang & Gotthelf (1998b) analysed ROSAT HRI observations and suggested that the emission could come from the remnants of a bow shock if the pulsar was moving with a velocity of $\sim$1000$\,\mathrm{km\,s^{-1}}$. Wang et al. (2001) subsequently analysed higher spatial resolution CHANDRA observations, which clearly delineated this emission and implied that the pulsar was moving away from VFTS102. See, however, Chen et al. (2006) for an alternative explanation of the X-ray morphology, which does not imply a high velocity for the pulsar. Fig. 3 superimposes these emission contours onto an HST optical image with VFTS102 being near the tail of these contours. As discussed by Wang et al. (2001) the spatial distribution of the diffuse X-ray emission and the SNR optical emission are well correlated. Differences probably arise from a foreground dark cloud and photoionization and mechanical energy input from the nearby open cluster.

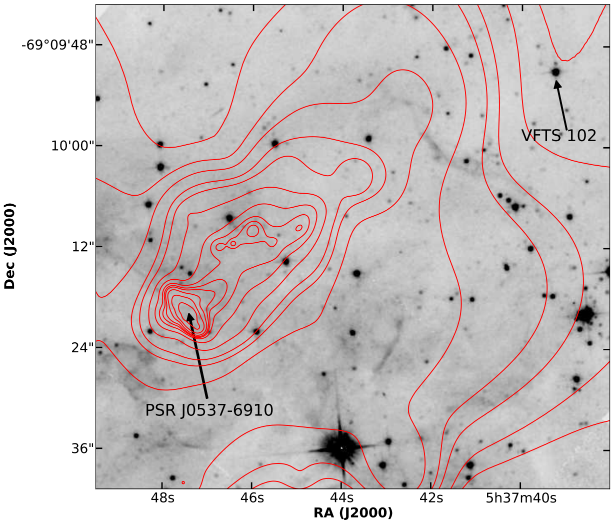

Figure 3. HST WFPC2 V-band (F606W filter) image with contours from the smoothed Chandra HRC-I image overlaid. The positions of VFTS102 and PSR J0537-6910 are labeled.

Timing measurements imply that the pulsar has a characteristic age of 5000 years (Marshall et al. 1998), consistent with the age estimate of Wang & Gotthelf (1998b) from analysis of X-ray emission. Spyrou & Stergioulas (2002) discuss the estimation of ages from spin rates and find the results to be sensitive to both the breaking index and the composition of the pulsar core. Indeed phase connected braking index measurements for young pulsars (see Zhang et al. 2001, and references therein) yield breaking indices lower than the n=3 normally adopted with corresponding increases in the characteristic ages. Additionally, Chu et al. (1992) found an age of approximately 24000 years from the kinematics of the supernova remnant.

Adopting an age of 5000 years would imply that if these objects had been part of a binary system, their relative velocity (v_{s}) in the plane of the sky would be approximately $2500\,\mathrm{km\,s^{-1}}$. Increasing this age to 24000 years would then imply $v_{\mathrm{s}} \sim 500\,\mathrm{km\,s^{-1}}$. These values although large are consistent with a pulsar velocity of $1000\,\mathrm{km\,s^{-1}}$ in the model of Wang & Gotthelf (1998b) and of $\sim$600$\,\mathrm{km\,s^{-1}}$ from the separation of the diffuse X-ray and radio emission (Wang et al. 2001). Additionally Hobbs et al. (2005) found a mean space velocity of approximately $400\,\mathrm{km\,s^{-1}}$ for a sample of young pulsars with velocities as high as $1600\,\mathrm{km\,s^{-1}}$. From the theoretical point of view, Stone (1982) found supernova kick velocities normally in excess of $300\,\mathrm{km\,s^{-1}}$, while more recently Eldridge et al. (2011) estimated kick-velocities for a single neutron star of more than $1000\,\mathrm{km\,s^{-1}}$with a mean value of $\sim$500$\,\mathrm{km\,s^{-1}}$.

4.2.2. *A binary evolution scenario for VFTS102*

While the fast rotation of VFTS102 might be the result of the star formation process, it could also have arisen from spin-up due to mass transfer in a binary system (Packet 1981). A subsequent supernova explosion of the donor star could then lead to an anomalous radial velocity for VFTS102 (Blaauw 1961; Stone 1982). The nearby pulsar and supernova remnant make this an attractive scenario. Of course, we cannot eliminate other possible scenarios, e.g. dynamical ejection from a cluster (see Gvaramadze & Gualandris 2011) but it is unclear whether these could produce the very large rotational velocity of VFTS102.

Cantiello et al. (2007) have modelled a binary system with initial masses of 15 and 16 $M_\odot$ adopting SMC metallicity. After mass transfer the primary exploded as a type Ib/c supernova. At that stage the secondary has a mass of approximately 21 $M_\odot$, a rotational velocity close to critical and a logarithmic luminosity of approximately 4.9 dex (see Fig. 2 for its subsequent evolution). These properties closely match the estimates for VFTS102 summarized in Table 1.

Based on grids of detailed binary evolutionary models (Wellstein et al. 2001; de Mink et al. 2007), the initial masses of the two components of such a binary system should be comparable, with $M_2/M_1 \gtrsim 0.7$. If the initial mass of the secondary was in the range of 14-18 $M_\odot$, that of the primary would need to be smaller than about 25 $M_\odot$. This agrees with the estimated initial mass of the supernova progenitor based on the kinematics of the supernova remnant (Micelotta et al. 2009).

In this scenario, it takes the primary star about 11 Myr to evolve to the supernova stage. While the most massive stars in 30 Doradus have ages of a few million years (Walborn et al. 1999), there is also evidence for different massive stellar populations with ages ranging up to about 10 Myr (Walborn & Blades 1997). Recently, De Marchi et al. (2011) have undertaken an extensive study of lower mass ($\lesssim 4\,M_\odot$) main sequence and pre-main sequence stars in 30 Doradus. They obtain a median age of 12 Myr with ages of up 30 Myr. Hence it would appear possible that the putative binary system formed in the vicinity of 30 Doradus approximately 10 Myr ago and underwent an evolutionary history similar to that modelled by Cantiello et al. (2007).

While the evolutionary link between VFTS102 and the pulsar is an attractive scenario, the offset between VFTS102 and the apparent center of the radio emission (see Wang et al. 2001) remains to be explained. Proper motion information would be extremely valuable to further test this hypothesis. PSR J0537-6910 has not been definitely identified in other wavelength regions. Mignani et al. (2005) using ACS imaging from the Hubble Space telescope found two plausible identifications that would imply an optical luminosity similar to the Crab-like pulsars. A radio survey by Manchester et al. (2006) only yielded an upper limit to its luminosity consistent with other millisecond pulsars. However estimates for both components may be obtained from the HST proper motion study (Programme: 12499; PI: D.J. Lennon) that is currently underway.

4.3. *Evolutionary future*

Irrespective of the origin of VFTS102, it is interesting to consider its likely fate. Stellar evolutionary models of rapidly rotating stars have recently been generated by Woosley & Heger (2006) and Yoon et al. (2006). The latter consider the fate of objects with rotational velocities up to the critical value (v_c). The evolution is shown to depend not only on initial mass and rotational velocity but also on the metallicity. In particular GRBs are predicted to occur only at sub-solar metallicities.

Based on our single star models, VFTS102 has a rotational velocity above $\sim 0.8 v_c$ and is thus expected to evolve quasi-chemically homogeneously. While Yoon et al. (2006) and Woosley & Heger (2006) estimate the metallicity threshold for GRB formation from chemically homogeneous evolution to be somewhat below the LMC metallicity, the latter note its sensitivity to the mass loss rate (Vink & de Koter 2005). Indeed all our most rapidly rotating $20 - 30\,M_\odot$ models are evolving chemically homogeneously throughout core hydrogen burning (Fig. 2), a prerequisite to qualify for a GRB progenitor. In any case, within the context of homogeneous evolution VFTS102 is expected to form a rapidly rotating black hole, and a Type Ic hypernova. This conjecture remains the same within the binary scenario of Cantiello et al. (2007).

Assuming a space velocity of $40\,\mathrm{km\,s^{-1}}$ for VFTS102 (compatible with its anomalous radial velocity), our evolutionary models imply that VFTS102 will travel ~300-400 pc before ending its life. This is consistent with the finding of Hammer et al. (2006) that the locations of three nearby GRBs were found several hundred parsecs away from their most likely progenitor birth locations (see, however, Margutti et al. 2007; Wiersema et al. 2007; Han et al. 2010).

5. CONCLUSIONS

VFTS102 has a projected rotational velocity far higher than those found in previous surveys of massive stars in the LMC, and indeed it would appear to qualify as the most rapidly rotating massive star yet identified. With a luminosity of $10^5\,L_\odot$ we estimate its current mass to be approximately 25 $M_\odot$. Its extreme rotation, peculiar radial velocity, proximity to the X-ray pulsar PSR J0537-6910 and to a supernova remnant suggest that the star is the result of binary interaction.

It is proposed that VFTS102 and the pulsar originated in a binary system with mass transfer spinning-up VFTS102 and the supernova explosion imparting radial velocity kicks to both components. If evolving chemically homogeneously, as suggested by recent models, VFTS102 could become a GRB or hypernova at the end of its life. Additionally it may provide a critical test case for chemically homogeneous evolution.
